ABSTRACT

In the automata theoretic approach to explicit state LTL model checking, the synchronized product of the model and an automata that represents the negated formula is checked for emptiness. In practice, a (generalized) Büchi automaton (GBA) is constructed and used for this procedure.

This paper investigates whether using a more general form of automaton, a generalized Rabin automaton (GRA), improves the model checking procedure. An advantage of using a GRA is that its number of states can be significantly less than that of a GBA. Unlike a GBA, a GRA can also deterministically represent any LTL formula. However, the corresponding emptiness checking procedure is more involved. With recent advances in probabilistic model checking and LTL to GRA translators, it is only natural to ask whether checking a GRA directly is more advantageous in practice.

We designed a multi-core GRA checking algorithm and performed experiments on a subset of the models and formulas from the 2015 Model Checking Contest. Findings include that our algorithm can be used as a replacement for a GBA checking algorithm without losing performance. We also report advantages and disadvantages of using our algorithm to check TGRAs directly.

1. INTRODUCTION

Model checking.

In the automata theoretic approach to LTL model checking, the synchronized product of the negated property and the state-space of the system is combined. The resulting product is checked for emptiness by searching for an *accepting cycle*, i.e., a reachable cycle that satisfies the accepting condition [27]. The emptiness checking procedure is limited

by the well-known *state-space explosion*, where the product automaton becomes too large to handle.

On-the-fly model checking mitigates the state-space memory constraints by only storing the states (not the transitions) encountered during the emptiness check. The search procedure is launched from an initial state, and in case a counterexample is detected it may end well before the entire state-space is explored. A consequence is that in practice emptiness checks rely on *depth-first search (DFS)* exploration [26].

Another way to reduce the size of the product automaton is to keep the sizes of the system's state-space and the negated property automaton as small as possible. In particular, smaller property automata can be obtained by using more complex acceptance conditions.

With current hardware systems one can further improve the model checking performance by utilizing multiple cores. This way, the time to model check can be significantly reduced; related work shows that even though the problem is difficult to parallelize, in practice an almost linear improvement with respect to the number of cores can be obtained [17, 14, 25, 6].

Our goal: emptiness checks using generalized Rabin automata.

The automata-theoretic approach to LTL model checking is often performed using *Büchi automata* (BA), or even *transition-based generalized Büchi automata* (TGBA). TGBAs can be linearly more concise than BAs, resulting in smaller products, and can be emptiness checked using SCC-based algorithms at no extra cost (compared to SCC-based algorithms on BAs) [8].

For probabilistic model checking, working with deterministic automata is important, as otherwise the resulting product automaton might not be a Markov chain [3]. Since it is well known that not all BAs can be determinized, probabilistic model checkers have been working with *Rabin automata* (RA) instead. Recently, order-of-magnitude speedups were reported when performing probabilistic model checking using a generalized acceptance condition called *transition-based generalized Rabin Automata* (TGRA) [7]. At the same time, there has been a lot of interest into building tools such as LTL3DRA [2] and Rabinizer 3 [19, 13] for translating LTL formulas into small deterministic TGRAs.

Our objective is to study whether the speedups observed with TGRAs in probabilistic model checking also hold for non-probabilistic explicit model checking. While there are plenty of algorithms for checking BAs and TGBAs (both

sequentially and multi-core) [26, 14, 25, 6]. In the case for Rabin there is only a recent work on a GPU algorithm for checking (non-generalized) RAs [28] and a TGRA checking algorithm for probabilistic model checking [7].

None of these works address our question: is there any advantage to using *transition-based Generalized Rabin Automata* (TGRA) over *transition-based Generalized Büchi Automata* (TGBA)? To do so, we introduce a multi-core emptiness-check procedure for TGRA. We implemented it in LTSMIN [18], and benchmark several model-checking tasks realized using TGRA or TGBA. Note that in our case, the determinism of the automaton is not important.

We should also point out that having an efficient emptiness check for TGRA has more applications than just model checking, because the generalized Rabin acceptance can be thought of as a normal form for any acceptance condition. Such a TGRA emptiness check could therefore be useful to ω -automata libraries such as Spot [10] that work with automata using arbitrary acceptance conditions [1]. Currently, ω -automata are converted into TGBAs before being emptiness-checked. A recent tool is LTL3HOA, which produces automata with an arbitrary acceptance condition.

Overview.

The remainder of the paper is structured as follows. We provide preliminaries in Section 2 and present our algorithm in Section 3. We discuss related work in Section 4. Implementation details and experiments are discussed in Section 5 and we conclude in Section 6.

2. PRELIMINARIES

We define ω -automata using acceptance conditions that are positive Boolean formulas over terms like $\text{Fin}(T)$ (the transitions in T should be seen finitely often) or $\text{Inf}(T)$ (infinitely often). This convention, inspired from the HOA format [1] allows us to express all traditional acceptance conditions, and is similar to the formalism used by Emerson & Lei 30 years ago [12] using state-based acceptance.

DEFINITION 1 (TELA). *A transition-based Emerson-Lei automaton (TELA) is a tuple $\mathcal{A} = (\Sigma, Q, q_0, \delta, \text{Acc})$ where Σ is an alphabet, Q is a finite set of states, $q_0 \in Q$ is the initial state, $\delta \subseteq Q \times \Sigma \times Q$ is a transition relation, Acc is a positive Boolean function over terms of the form $\text{Fin}(T)$ or $\text{Inf}(T)$ for any subset $T \subseteq \delta$. For a transition $t \in \delta$ we note t^s its source, t^ℓ its label, and t^d its destination: $t = (t^s, t^\ell, t^d)$.*

The runs of \mathcal{A} are infinite sequences of consecutive transitions:

$$\text{Runs}(\mathcal{A}) = \{\rho \in \delta^\omega \mid \rho(0)^s = q_0 \wedge \forall i \geq 0 : \rho(i)^d = \rho(i+1)^s\}$$

The acceptance of a run ρ is defined by evaluating the acceptance condition Acc over ρ such that:

- $\text{Fin}(T)$ is true iff all the transitions in T occur finitely often in ρ .
- $\text{Inf}(T)$ is true iff some transitions in T occurs infinitely often in ρ .

Let $\rho^\ell \in \Sigma^\omega$ be the word recognized by a run $\rho \in \text{Runs}(\mathcal{A})$ defined by $\rho^\ell(i) = \rho(i)^\ell$ for all $i \geq 0$. The language of \mathcal{A} is the set of all words ρ^ℓ recognized by some accepting run ρ .

Figure 1: (\mathcal{A}_1) a deterministic transition-based generalized Büchi automaton recognizing $\text{GF}a \wedge \text{GF}b$. (\mathcal{A}_2) a non-deterministic transition-based Büchi automaton recognizing $\text{FG}a$. (\mathcal{A}_3) a deterministic transition-based co-Büchi automaton recognizing $\text{FG}a$.

A Transition-based Generalized Büchi Automaton (TGBA) is a TELA where $\text{Acc} = \text{Inf}(T_1) \wedge \text{Inf}(T_2) \wedge \dots \wedge \text{Inf}(T_n)$ for some n , meaning that any accepting run has to visit infinitely often one transition from each set T_i .

As an example, automaton \mathcal{A}_1 from Figure 1 represents a TGBA for the formula $\text{GF}a \wedge \text{GF}b$. Here, the formula is satisfied if both \bullet and \bullet are visited infinitely often. These marks respectively represent taking the actions a and b .

The two automata \mathcal{A}_2 and \mathcal{A}_3 from Figure 1 represent the formula $\text{FG}a$ using different acceptance conditions: \mathcal{A}_2 is a Transition-based Büchi Automaton while \mathcal{A}_3 is a Transition-based co-Büchi Automaton. Both automata are minimal in their number of states and illustrate that allowing Fin acceptance can reduce the size of the automaton. Moreover, \mathcal{A}_3 is a deterministic automaton, whereas no equivalent deterministic BA exists.

A Transition-based Generalized Rabin Automaton (TGRA) is a TELA where Acc has the form $\bigvee_{i=1}^n (\text{Fin}(F_i) \wedge \text{Inf}(I_1^i) \wedge \text{Inf}(I_2^i) \wedge \dots \wedge \text{Inf}(I_{\ell_i}^i))$ for some values of n , and $\ell_1, \ell_2, \dots, \ell_n$. This is a generalization of Rabin acceptance in the sense that in Rabin acceptance $\ell_i = 1$ for all i . Each conjunctive clause of the form $\text{Fin}(F_i) \wedge \text{Inf}(I_1^i) \wedge \text{Inf}(I_2^i) \wedge \dots \wedge \text{Inf}(I_{\ell_i}^i)$ is called a generalized Rabin pair (GRP).

Figure 2 depicts a deterministic TGRA (\mathcal{A}_4) and a non-deterministic TGBA (\mathcal{A}_5), both representing the property $\text{FG}(Fa \cup b)$. \mathcal{A}_4 is accepting if either \bullet is visited infinitely often without visiting \bullet infinitely often, or if \bullet is visited finitely often and both \bullet and \bullet are visited infinitely often. Only one of the two GRPs has to be satisfied. In this case, by comparing \mathcal{A}_4 and \mathcal{A}_5 we can (again) observe that Fin acceptance aids in both reducing the size of the automaton and causes the automata to be deterministic.

Since generalized Rabin acceptance is just a disjunction of GRPs, it can serve as a normal form for any acceptance condition. Any acceptance condition can be converted into generalized Rabin acceptance by distributing \wedge over \vee to obtain a disjunctive normal form, and then replacing any conjunctive clause of the form $\text{Fin}(F^1) \wedge \text{Fin}(F^2) \wedge \dots \wedge \text{Fin}(F^m) \wedge \text{Inf}(I^1) \wedge \text{Inf}(I^2) \wedge \dots \wedge \text{Inf}(I^\ell)$ by the GRP $\text{Fin}(\bigcup_{i=1}^m F^i) \wedge \text{Inf}(I^1) \wedge \text{Inf}(I^2) \wedge \dots \wedge \text{Inf}(I^\ell)$. This conversion can be done without changing the transition structure of the automaton; its only downside is that it may introduce an exponential number of GRPs.

DEFINITION 2 (SCC). *Given a TELA of the form $\mathcal{A} = (\Sigma, Q, q_0, \delta, \text{Acc})$, a partial Strongly Connected Component (partial SCC) is a pair $C := (C_Q, C_\delta) \in 2^Q \times 2^\delta$ with $C_Q \neq \emptyset$ such that any ordered pair of states of C_Q can be connected by a sequence of consecutive transitions from C_δ . We say*

Figure 2: Two automata recognizing $FG(Fa \cup b)$. (A_4) a deterministic transition-based generalized-rabin automaton with two pairs. (A_5) a non-deterministic transition-based generalized Büchi automaton.

that C is a maximal SCC if C is maximal with respect to inclusion, thus the case where both C_Q and C_δ cannot be extended. An SCC is called trivial if $C_\delta = \emptyset$, and hence C_Q consists of a single state.

In a TGBA with n acceptance sets of the form $\text{Inf}(T_1) \wedge \dots \wedge \text{Inf}(T_n)$, finding an accepting run boils down to searching for a trace from the initial state to a reachable partial SCC C for which $\forall_{1 \leq i \leq n} : T_i \cap C_\delta \neq \emptyset$ holds, i.e., a partial SCC that intersects each acceptance set.

An accepting run on a GRP with Acc of the form $\text{Fin}(F) \wedge \text{Inf}(I^1) \wedge \text{Inf}(I^2) \wedge \dots \wedge \text{Inf}(I^\ell)$ is found by searching for a trace from the initial state to a reachable partial SCC C for which $\forall_{1 \leq i \leq \ell} : I_i \cap C_\delta \neq \emptyset$ and $F \cap C_\delta = \emptyset$ hold, i.e., a partial SCC that contains a transition from every Inf set and no transition from the Fin set.

Note that it is always valid in a TGBA to take C_δ (and C_Q) to be maximal with respect to inclusion. In the case for a TGRA this is not always the possible since Fin transitions must be prevented in C_δ . In case a Fin transition cannot be avoided in C_δ , then C cannot be an accepting SCC.

3. ALGORITHM FOR TGRA EMPTINESS

In this section we present an algorithm for checking emptiness on TGRAs. We start by splitting up the TGRAs into individual generalized Rabin pairs, and show how these can be checked efficiently.

3.1 Checking each Rabin pair separately

Checking TGRAs can be achieved by checking each Rabin pair separately, as shown in Algorithm 1. In case an accepting cycle is found in the GRPACC, that sub-procedure should report Acc and exit. Thus, in case none of the GRPACC sub-procedures report acceptance, the algorithm returns with No_Acc. We assume that prior to each GRPACC call, we have no knowledge on the individual GRPs and therefore treat them equally and separately. In theory, this assumption may lead to missed opportunities. For example, consider the case where $\text{GRP}_1 = \text{GRP}_2$, or even an overlap in the Fin and/or Inf fragments of the GRPs could be a reason for combining gained information.

Parallel GRA checking.

After a GRPACC call has finished, the next Rabin pair is selected and a new sub-procedure is started, until all n

Algorithm 1: Checking GRA by checking each GRP

```

1 function TGRACHECK ( $Q, q_0, \text{TGRA} = \{\text{GRP}_1, \dots, \text{GRP}_n\}$ )
2   forall  $i \in \{1, \dots, n\}$  do
3     GRPACC( $Q, q_0, \text{GRP}_i$ )
4   return No_Acc // No GRPACC call reported Acc

```

pairs have been checked. Since we are working in a multi-core environment, we can assign different worker instances to different Rabin pairs. Suppose there are P workers available, we can choose to either use all P workers for checking a single Rabin pair, or we can distribute the workers over the different pairs. By distributing the workers evenly, for n Rabin pairs, each pair is checked by $\frac{P}{n}$ workers.

One advantage of checking each pair in parallel is that the total workload can be better spread out over the available workers, i.e., there is less contention in the data structures since the probability of interfering with different search instances is reduced. Another advantage could be that counterexamples may be detected faster in this setting; suppose for example that only the n th pair contains a counterexample, assuming that the counterexample is detected by visiting only part of the state-space, this prevents the complete state-space from being searched $n - 1$ times.

A disadvantage is that the data structures used have to be copied for every Rabin pair search. This means that by checking all pairs in parallel, approximately n times more memory is required¹.

3.2 GRP checking algorithm

Throughout this section we consider checking a GRP with acceptance of the form $Acc = (F, \mathcal{I} = \{I^1, \dots, I^\ell\})$.

Abstract idea of the algorithm.

The general idea of the algorithm, which we present in Algorithm 2, is to perform an SCC computation on the graph without allowing any F transitions from being part of the SCCs. As a result, we obtain SCCs that contain all edges except for the F transition ones. Formally, we have that each SCC C is a partial SCC that is maximal on the GRP $\mathcal{A}_{\delta \setminus F} := (\Sigma, Q, q_0, \delta \setminus F, Acc)$. C is an accepting SCC if $\forall_{1 \leq i \leq \ell} : C_\delta \cap I^i \neq \emptyset$, i.e., every I^i set intersects the transitions of C . By definition of $\mathcal{A}_{\delta \setminus F}$, we have that $C_\delta \cap F = \emptyset$. If C is also reachable from q_0 via transitions from δ (including F transitions), it can be reported as a counterexample.

Preventing F transitions to be considered.

The algorithm detects the above-mentioned ‘constrained’ SCCs in linear time and in an on-the-fly setting, without relying on visiting states multiple times². It does so by performing a constrained SCC decomposition of \mathcal{A} from q_0 . Once a transition $t = (t^s, t^\ell, t^d) \in F$ is encountered, state t^d is stored in a so-called **Fstates** set and t is further disregarded since t cannot appear in any accepting cycle. Once

¹All global (shared) data structures have to be copied for the n pairs, but the memory overhead for the local data structures remains the same.

²The parallel search is based on swarmed verification, making it unlikely that states are visited only once in practice, but in theory and in a sequential setting this is not necessary for correctness.

Figure 3: Example of running an emptiness check on an GRA with two pairs. C_1 , C_2 , and C_3 represent components (not necessarily strongly connected) that do not contain any transition in the sets $\mathbb{0}$ or $\mathbb{3}$. Workers doing the emptiness check for the first pair will first explore $C_1 \cup C_3$, attempting to find a cycle satisfying $\text{Inf}(\mathbb{1}) \wedge \text{Inf}(\mathbb{2})$ without crossing the $\mathbb{0}$ -transitions leading to u and t . If no accepting cycles are found, they will continue their exploration in C_2 , starting in states u and v , and ignoring all transitions going back to $C_1 \cup C_3$. Workers doing the emptiness for the second pair, will similarly first look for cycles satisfying $\text{Inf}(\mathbb{4})$ in $C_1 \cup C_2$, postponing the exploration of C_3 that is only accessible via a $\mathbb{3}$ -transition.

this search is finished, all states are marked as **Dead** and all SCCs are decomposed on the subgraph \mathcal{A}' , which is formed by a reachability from q_0 over the transitions $\delta \setminus F$. In case a non-trivial SCC contains transitions from all I^i sets we have detected a counterexample. Otherwise, we pick a state s from the **Fstates** set and repeat the same procedure (using $q_0 := s$). For this state s there are two cases:

1. s is marked **Dead**, meaning that it was added to **Fstates** but it was also reachable in \mathcal{A}' (without taking any F transitions). Thus, we have already addressed this state and can ignore it. The state s is correspondingly removed from **Fstates**.
2. s is not marked **Dead**, meaning that s is not part of \mathcal{A}' and we launch a new SCC decomposition from s .

The search procedure is illustrated in [Figure 3](#). Here, two GRPs are checked separately. Note that due to the way how $\mathbb{0}$ and $\mathbb{3}$ are located in the automaton, the initial searches for the first and second pair lead to different components. The search for pair 1 detects $\mathcal{A}'_1 = C_1 \cup C_3$ (avoiding $\mathbb{0}$) and the search for pair 2 detects $\mathcal{A}'_2 = C_1 \cup C_2$ (avoiding $\mathbb{3}$). Consider the search for pair 1, after the initial search it found the **Fstates** u and t . Both have not been explored so suppose that u is arbitrarily chosen as a ‘new’ initial state. We assume that the search from u visits all states in C_2 ³. If now the edge is found from v to r , thus from C_2 to C_1 ,

³Consider for example what happens when there is no path from u to t . After the search for u ends, all reachable states from u are marked **Dead** and the search from t is started. Once it observes a **Dead** state it will not continue searching that state, hence no redundant states are explored.

we must not allow this transition to form a cycle as it would contain the $\mathbb{0}$ mark. Since the search from u is initiated *after* the search from q_0 is complete, r is already marked **Dead** and thus ignored. In fact, even when we allow the search from u to start before all states in $C_1 \cup C_3$ are marked **Dead** it may in the worst case only add redundant explorations. This is because the edge from s to u is never really considered as an edge in the SCC decomposition and hence no cycle can be formed with a $\mathbb{0}$ mark.

Algorithm 2: Algorithm for checking a GRP

```

1 function GRPACC ( $Q, q_0, \text{GRP} = (F_M, \mathcal{I}_M)$ )
2    $\forall s \in Q : \mathcal{S}(s) := (\{s\}, \emptyset)$  // Initialize map
3   Visited := Dead :=  $\emptyset$  // Sets
4    $R := \emptyset$  // Roots stack of ( $\text{acc}, \text{state}$ ) pairs
5   Fstates :=  $\{q_0\}$  // Cyclic list of init states
6   while  $\neg$ Fstates.isEmpty() do
7      $s :=$  Fstates.pickState()
8     if  $s \notin$  Dead then GRPACCRECUR( $\emptyset, s$ )
9     Fstates.removeState( $s$ )
10  return // No Acc got reported in the search
11
12 function GRPACCRECUR ( $\text{acc}_s, s$ )
13   Visited := Visited  $\cup$   $\{s\}$ 
14    $R.$ push( $\text{acc}_s, s$ )
15   forall ( $\text{acc}_t, t \in \text{succ}(s)$ ) do
16     if  $t \in$  Dead then continue // Explored
17     else if  $t \notin$  Visited then // ‘New’ state
18       if  $\text{acc}_t \cap F_M \neq \emptyset$  then // Avoid  $F$ 
19         Fstates.addState( $t$ )
20       else GRPACCRECUR( $\text{acc}_t, t$ )
21     else if  $\text{acc}_t \cap F_M = \emptyset$  then // Cycle
22       while  $\mathcal{S}(s) \neq \mathcal{S}(t)$  do
23         ( $\text{acc}_r, r$ ) :=  $R.$ pop()
24         Unite( $\mathcal{S}, r, R.$ top().state)
25         AddAcc( $\mathcal{S}, r, \text{acc}_r$ )
26         AddAcc( $\mathcal{S}, s, \text{acc}_t$ ) // Add  $\text{acc}_t$  to  $\mathcal{S}(s)$ 
27         if  $\mathcal{I}_M = \mathcal{S}(s).$ acc then // Acc. cycle
28           report Acc and exit
29   if  $s = R.$ top() then // Completed SCC
30     Dead := Dead  $\cup$   $\mathcal{S}(s).$ states
31      $R.$ pop()

```

Data structures.

To represent the Fin and Inf fragments of a GRP, we use a set of accepting marks per transition. We assign a unique marking to each F and I^i set, for $1 \leq i \leq \ell$, and refer to these markings with F_M and I_M^i (and \mathcal{I}_M for $\bigcup_{1 \leq i \leq \ell} I_M^i$). The complete set M is thus defined as $M := \{F_M, I_M^0, \dots, I_M^\ell\}$. Each transition t is combined with an acceptance set $\text{acc} \subseteq M$, indicating whether $t \in F$ or $t \in I^i$ for $1 \leq i \leq \ell$.

We define \mathcal{S} as a mapping from states to pairs, consisting of a set of states and an acceptance set. Thus $\mathcal{S}(s) = (\text{states}, \text{acc})$ and formally, $\mathcal{S} : Q \rightarrow 2^Q \times 2^M$. By implementing \mathcal{S} with a union-find structure, we can maintain the following invariant at all times:

$$\forall u, v \in Q : u \in \mathcal{S}(v).\text{states} \Leftrightarrow \mathcal{S}(v) = \mathcal{S}(u)$$

This further implies that every state is part of exactly one set of states. \mathcal{S} pairs can be combined using a `Unite` function. We use an example to illustrate \mathcal{S} and the `Unite` function. Let $\mathcal{S}(u) := \{\{u, w\}, \{F_M\}\}$ and $\mathcal{S}(v) := \{\{v\}, \{F_M, I_M^1\}\}$, we can use the `Unite` function to combine the two structures. After calling `Unite`(\mathcal{S}, u, v) we have $\mathcal{S}(u) = \mathcal{S}(v) = \{\{u, v, w\}, \{F_M, I_M^1\}\}$, while keeping all other mappings the same. For more details on this structure, we refer to Bloemen et al. [5]. We use an additional function `AddAcc` to ‘add’ (the union of) acceptance marks to the set, thus `AddAcc`($\mathcal{S}, v, \{I_M^1, I_M^2\}$) will ensure that $\mathcal{S}(v).acc$ becomes $\{F_M, I_M^1, I_M^2\}$.

The `Fstates` structure is implemented as a cyclic list that contains all states added to the list (by means of `Fstates.addState`). `Fstates.pickState` returns a state from the list, in case the list is nonempty. Finally, states are removed from the list by calling `Fstates.removeState`. For efficient list containment and to avoid duplicated states from being added, we store the list on top of an array, in which the elements point to each other.

Detailed algorithm.

The sequential algorithm for checking a GRP is presented in Algorithm 2. First, all data structures are initialized in lines 2-5. Then, the algorithm continuously picks a state s (initially q_0) and calls the `GRPACCURECUR` procedure. After this procedure is finished, s is removed from the `Fstates` list and a new state is picked from the list. If the list is empty, we assume that the complete state-space has been visited and since no `Acc` was reported, we can conclude that no counterexample exists for this GRP and the algorithm returns.

In the `GRPACCURECUR` procedure, state s is marked as visited and pushed on top of the R stack, along with the accompanying acceptance set acc_s (note that since there is no transition to the initial state, the empty set is given in line 8). The R stack can be regarded as an extension to the *roots* stack from Dijkstra’s SCC algorithm [9]. All successors of s are considered in lines 15-28. For each successor t we consider three cases:

- $t \in \text{Dead}$ (line 16), this implies that t has already been completely explored and can thus be disregarded.
- t is unvisited (lines 17-20), meaning that t has not been encountered yet. If t is part of the `Fin` set, we add it to the `Fstates` list and ignore it for the current search. Otherwise, we recursively search t .
- t is not `Dead` but it has been visited before (lines 21-28). This implies that there is some state r' on the R stack such that $t \in \mathcal{S}(r').states$ and hence a cycle can be formed. The algorithm then continuously takes the top two states from the R stack and unites them together (and adds the acceptance mark) until $\mathcal{S}(s)$ and $\mathcal{S}(t)$ are the same. Finally, the acceptance marks from acc_t are added. At line 27, $\mathcal{S}(s)$ contains all states on the cycle from s to t and forms a partial SCC. $\mathcal{S}(s)$ is then checked if it contains all `Inf` acceptance marks. If so, an accepting SCC is found and is reported.

After all successors are explored, the algorithm backtracks. In case s equals the top of the R stack (line 29), s is the last state of the SCC and the entire SCC is marked as being fully explored by marking it as `Dead`.

Outline of correctness.

We argue that the `GRPACC` algorithm decomposes the GRP automaton in maximal SCCs when defined over the transitions $\delta \setminus F$ and that it correctly reports accepting cycles; it reports `Acc` when a reachable SCC contains a transition from each I^i sets, for $1 \leq i \leq \ell$, and no transition from F . Due to the conditions of line 18 and 21, for a transition with $acc_t \cap F \neq \emptyset$ it is not possible to start a recursive call with acc_t (thus acc_t never appears on the R stack) nor is it possible to call `AddAcc` with acc_t as an argument. All such transitions are ‘avoided’ and unvisited successors are added to `Fstates`. We thus conclude that no F transition can be contained in any formed SCC.

Because we do allow and explore all other (non- F) transitions during the search, assuming a correct SCC algorithm, the acceptance set of each SCC cannot be further extended without also having to include an F transition.

Since all states that did not get visited were added to the `Fstates` list, and each state from this list is eventually picked as an initial state, we argue that the complete state-space has been explored after the algorithm terminates.

Complexity.

One can observe that every state and transition is visited at most once in the algorithm. The `GRPACCURECUR` procedure will mark a state as visited and will never be called twice for the same state. The bottleneck of the algorithm becomes maintaining the \mathcal{S} structure. From [5] we have that the union-find structure (without tracking acceptance marks) causes the complete algorithm to operate in quasi-linear time. By assuming that $|M|$ ($= 1 + \ell$) is a small constant (which can be assumed in practice), tracking the acceptance can be achieved in constant time per modification to the structure, hence the total time complexity is upper bounded by $O(|M| \cdot |\delta| \cdot \log(|\delta|))$ for each GRP.

The space complexity is limited by the sizes of the R , \mathcal{S} , and `Fstates` structures. R may contain up to $|Q|$ states and acceptance marks in the worst case (by visiting every state in a single path). \mathcal{S} can be implemented as an array of length $|Q|$ of structs that are of constant size, plus $|M|$ bits for tracking acceptance, and `Fstates` can be implemented as an array of $|Q|$ elements. In total $O(|Q| \cdot |M|)$ memory is used.

Parallel implementation.

Algorithm 2 can be parallelized by *swarming* the search instances; by starting multiple worker instances from the initial state and using a randomized successor function to steer the workers towards different parts of the state-space. The `GRPACCURECUR` function can be seen as an extension to the multi-core SCC algorithm from Bloemen et al. [5, 6]. The key to this algorithm is to *globally* communicate *locally* detected cycles. This way, multiple workers can cooperatively decompose SCCs. Additionally, (partly) unexplored states in an SCC are tracked globally and once a worker fully explores a state, none of the other workers have to explore this state again. Once all states of an SCC are fully explored, the entire SCC must be fully explored and thus can be marked `Dead`.

During `Unite` procedures, the involved parts of the union-find structure are briefly locked to guarantee correctness. During this locking phase, the acceptance set can be updated atomically without interfering with other parts. This is also

implemented in the TGBA checking algorithm from [6].

The `Fstates` list is implemented by using a fine-grained locking mechanism to add states to the list, such that all states remain on the cycle. The reason for implementing `Fstates` as a cyclic list becomes clear in the next example. Suppose the `Fstates` list contains two states, u and v . To avoid contention, the algorithm attempts to divide the workload by assigning half of the workers to search from u and the other half to search from v . Now, assume that u does not have any successors and a large part of the state-space is reached from v . If the search from u completes, we ideally want to let the workers aid in the search from v . By maintaining `Fstates` as a cyclic list, without much effort we can check which searches have not been completed yet. The `Fstates` list is implemented similarly as the cyclic list in the union-find structure, which is discussed in [5].

The time complexity of the algorithm is in the worst case increased by a factor P , for P workers, since the algorithm tracks a bit per worker instance in the union-find structure. However, in practice we observe an improvement over the sequential implementation. For the same reason the memory complexity is also increased by P , and additionally every worker contains its own R stack. Moreover, as mentioned in Section 3.1, if all Rabin pairs are checked simultaneously, the global data structures have to be copied. As a result, n times more memory is required for these structures, in case there are n Rabin pairs.

4. RELATED WORK

Related work on checking Büchi automata.

Explicit state on-the-fly algorithms for checking can be distinguished in two classes, namely *Nested Depth-First Search (NDFS)* and *SCC-based* algorithms [26]. The advantage of SCC-based algorithms over NDFS is that they can handle *generalized* Büchi automata efficiently.

In a multi-core setting, we consider the CNDFS algorithm [14] to be the state-of-the-art NDFS-like algorithm. It is based on *swarm verification* [16] and operates by spawning multiple NDFS instances and globally communicating ‘completed’ parts of the state-space.

For state-of-the-art multi-core SCC-based algorithms, in prior work we showed that the algorithm from Bloemen et al. [6] outperforms other techniques. This technique is also based on swarmed searches, and detected partial SCCs are communicated globally and maintained in a shared structure. Notable related multi-core SCC algorithms are the ones from Renault et al. [25] and Lowe [23].

Related work on checking Rabin automata.

As mentioned in Section 1, when checking LTL properties for probabilistic systems, the automaton needs to be deterministic [3]. Chatterjee et al. [7] present an algorithm to check deterministic GRA conditions in the context of (offline) probabilistic model checking. The idea is to consider each generalized Rabin pair $(F_i, \{I_i^1, \dots, I_i^{l_i}\})$ separately and for each pair: (1) remove the set of states F_i from the state space, (2) Compute the maximal end-component (MEC) decomposition, and (3) check which MECs have a non-empty intersection with every I_i^j , for $j = 1, \dots, l_i$. These sets are then used for computing maximal probabilities. The paper reports significant improvements over check-

ing a degeneralized variant of deterministic GRAs. They also present improvements for computing a winning strategy in LTL(F,G) games by using a fixpoint algorithm for generalized Rabin pairs. Our algorithm is different in that it operates on-the-fly and in a multi-core setting.

Wijs [28] recently presented a on-the-fly GPU algorithm for checking LTL properties for non-generalized deterministic Rabin automata. Here, the choice for (deterministic) Rabin automata, instead of non-deterministic Büchi automata, is motivated by the observations that it can speed up the successor construction and that it can reduce the state space of the cross-product. He uses a BFS-based search technique, in particular a variation on the heuristic *piggybacking* search [17, 15]. This approach is incomplete due to situations referred to as *shadowing* and *blocking*, but these cases can be detected and resolved with a depth-bounded DFS. Our approach differs in that we allow (generalized) TGRAs and do not require repair procedures.

Related work on checking different automata.

Emerson and Lei [12] show that the emptiness check of an ω -automaton with arbitrary acceptance condition is NP-complete. They also present a polynomial algorithm for the case where the acceptance condition is provided as a disjunction of Streett acceptance conditions. Streett acceptance is the negation of Rabin acceptance, a conjunction of $\text{Fin}(I) \vee \text{Inf}(F)$ instances (or equivalent, $\text{Inf}(I) \Rightarrow \text{Inf}(F)$), and Streett acceptance closely relates to fairness checking.

Duret-Lutz et al. [11] present a sequential algorithm for checking Streett objectives by performing an SCC decomposition and tracking thresholds to prevent ‘rejecting’ cycles from occurring in the SCCs. In a multi-core setting, the algorithm by Liu et al. [22] performs an initial SCC decomposition and for every SCC a new instance is launched in parallel that ignores certain transitions.

5. EXPERIMENTS

5.1 Experimental Setup

All experiments were performed on a machine with 4 AMD Opteron™ 6376 processors, each with 16 cores, forming a total of 64 cores. There is a total of 512GB memory available. We performed all experiments using 16 cores.

implementation.

The TGRA checking algorithm is implemented in the LTSMIN toolset [18]. We used several external tools and libraries for generating and parsing the automata:

- **Spot v2.3** [10], we used the spot tools `ltl2tgba` for generating TGBAs and `autfilt` for translating automata to TGRAs (using `autfilt --generalized-rabin`).
- **cpphoafparser v0.99.2⁴**, we used this library to parse a HOA automaton and create an internal representation for representing automata in LTSMIN.
- **Rabinizer v3.1** [19, 13], we used this tool to generate deterministic transition-based generalized Rabin automata.

⁴Available on <http://automata.tools/hoa/cpphoafparser>.

- **LTL3DRA v0.2.4** [2], we used this tool to also generate deterministic automata with transition-based generalized Rabin acceptance, but **LTL3DRA** only supports a subset of LTL, called **LTL\GUX** in [4], which is slightly stricter than the set of LTL formulas where no *until* (U) operator may occur in the scope of any *always* (G) operator.
- **LTL3HOA v1.0.1**⁵, we used this tool to generate non-deterministic automata with an arbitrary complex transition-based acceptance. We used `autfilt --generalized-rabin` to translate these automata to TGRAs.

We used the algorithm from Bloemen et al. [6] to model check TGBAs, and used the algorithm presented in this paper for checking TGRAs, both are implemented in **LTSMIN**. The algorithms make use of **LTSMIN**'s internal shared hash tables [21], and the same randomized successor distribution method is used throughout. The shared hash table is initialized to store up to 2^{28} states.

Experiments.

We took models and LTL formulas from the 2015 Model Checking Contest [20]. We restricted this set of over 44,000 pairs of models and formulas to those that do not describe obligation properties [24] because using non-Büchi acceptance cannot help producing smaller automata on this class. This selection is further reduced by selecting only the instances where the ‘TGRA generators’ (**LTL3DRA**, **Rabinizer 3** and **LTL3HOA**) create TGRAs with at least one non-empty Fin set. Otherwise, a GRP is the same as a TGBA, and hence the TGBA emptiness check could be used instead. For this selection, we report results on the experiments (80 in total) for which the time to model check using the TGBA checking algorithm is between 1 second and 10 minutes. We remark that this selection is in favor of the TGBA checking algorithm, since all timeouts and memory errors were filtered out automatically.

For each pair of model M and formula φ we solved the model checking task $\mathcal{L}(M \otimes A_{-\varphi}) = \emptyset$ using 5 configurations that were repeated 10 times. The configurations were: `lt12tgba` using the TGBA checking algorithm, **LTL3DRA**, **Rabinizer 3**, **LTL3HOA** translated to TGRA, and `lt12tgba` translated to a TGRA, where the latter four cases used the TGRA checking algorithm introduced in this paper. Every task was run with a timeout of 10 minutes. In total the experiments took approximately 5 days to complete.

All our results and means to reproduce the results are available on <https://github.com/utwente-fmt/Rabinizer3>.

5.2 Main results

The main results of the experiments are presented in [Figure 4](#) and are summarized in [Table 1](#). One thing to note is that the results are presented on a log-log scale. The (16-core) experiments for the TGBA checking algorithm are provided on the x-axis and the results for the four GRP checking experiments are given on the y-axis. The time for each experiment was repeated 10 times and averaged. All TGRAs are checked by considering each GRP sequentially, i.e., all workers are assigned to the first GRP and continue

to the second pair (if there is one) when the first GRP is fully explored.

We encountered a couple of errors in the experiments. There were two instances that resulted in a memory error, meaning that too much memory was allocated during the model checking procedure. These errors only occurred for the TGRA checks and were caused by the additional allocation of the **Fstates** data structure. There are also two instances that resulted in timeouts for some of the configurations. These both contain counterexamples and suggest that having Fin acceptance instead of only Inf can sometimes lead to bad performance for the TGRA checking algorithm.

Comparison with *Rabinizer 3* and *LTL3DRA*.

We observe that most of the results for **Rabinizer 3** and **LTL3DRA** (and to some extent also **LTL3HOA**) are similar to each other. This could be explained by the fact that both translators produce (deterministic) GRAs that likely do not differ much. We observe that on average, in [Table 1](#), the TGBA checking algorithm performs 37% faster when compared to **Rabinizer 3** and 49% faster when compared to **LTL3DRA**. We highlight a couple of instances.

Arguable the worst performing model is the one at (x,y) position (119,503) in the top-right scatter plot, meaning that the GRA checking algorithm took 503 seconds to complete, while the TGBA checking algorithm performed 4.2 times faster. The corresponding TGBA consists of 1 acceptance set and the GRA is a single pair with a nonempty Fin set and no Inf sets (i.e., a co-Büchi automaton). On further analysis we find that the GRA even contains fewer transitions, namely $1.05 \cdot 10^9$ compared to $1.23 \cdot 10^9$ of the TGBA. However, over 15% of the transitions in the GRA are part of the Fin set. As a result, the performance deficit is likely caused by the overhead of maintaining the **Fstates** in the algorithm. This instance can be found in the comparisons with **Rabinizer 3** and **LTL3HOA** as well, with similar results.

A better instance is the one at (9.2,6.5) in the top-right scatter plot. In this case, we also have a TGBA with 1 acceptance set and a GRA that equals a co-Büchi automaton. While we again have that the number of **Fstates** forms a significant part of the total number of transitions (15%), the difference here is that the total number of transitions is much smaller. In total, the TGBA has $1.4 \cdot 10^6$ transitions and the GRA has $0.6 \cdot 10^6$ transitions. This significant difference with the previous instance is explained by the combination of a costly successor function and the checking times are also reduced by at least a factor of 10. We argue that the GRA checking algorithm takes advantage of the reduced state-space in this instance to outperform the TGBA checking algorithm.

Comparison with *LTL3HOA*.

We consider a comparison with the automata produced by **LTL3HOA** different from the previous two discussed configurations, since **LTL3HOA** produces automata with a generic acceptance that are not necessarily deterministic. We observed that Fin sets are more often found in TGBAs created from the **LTL3HOA** instances compared to those from the LTL-to-GRP translators, hence there are more experiments shown in the scatter plot.

The results show instances that perform very poorly compared to the TGBA checking algorithm, but there are also cases, especially counterexamples, that are solved much

⁵Available on <https://github.com/jurajmajor/ltl3hoa>.

Table 1: Comparison of the geometric mean execution times (in seconds). The numbers between parentheses denote how many times faster the TGBA checking algorithm is compared to the other configuration. We only used the times from experiments that were checked in *all* configurations (25 in total, of which 2 counterexamples).

	LTL3HOA	LTL3DRA	Rabinizer 3	TGBA-TGRA	TGBA
Counterexample	8.40 (5.42)	8.04 (5.19)	2.83 (1.83)	1.63 (1.05)	1.55
No counterexample	12.91 (1.33)	12.99 (1.33)	12.96 (1.33)	10.08 (1.04)	9.73
Total	12.47 (1.48)	12.50 (1.49)	11.48 (1.37)	8.71 (1.04)	8.40

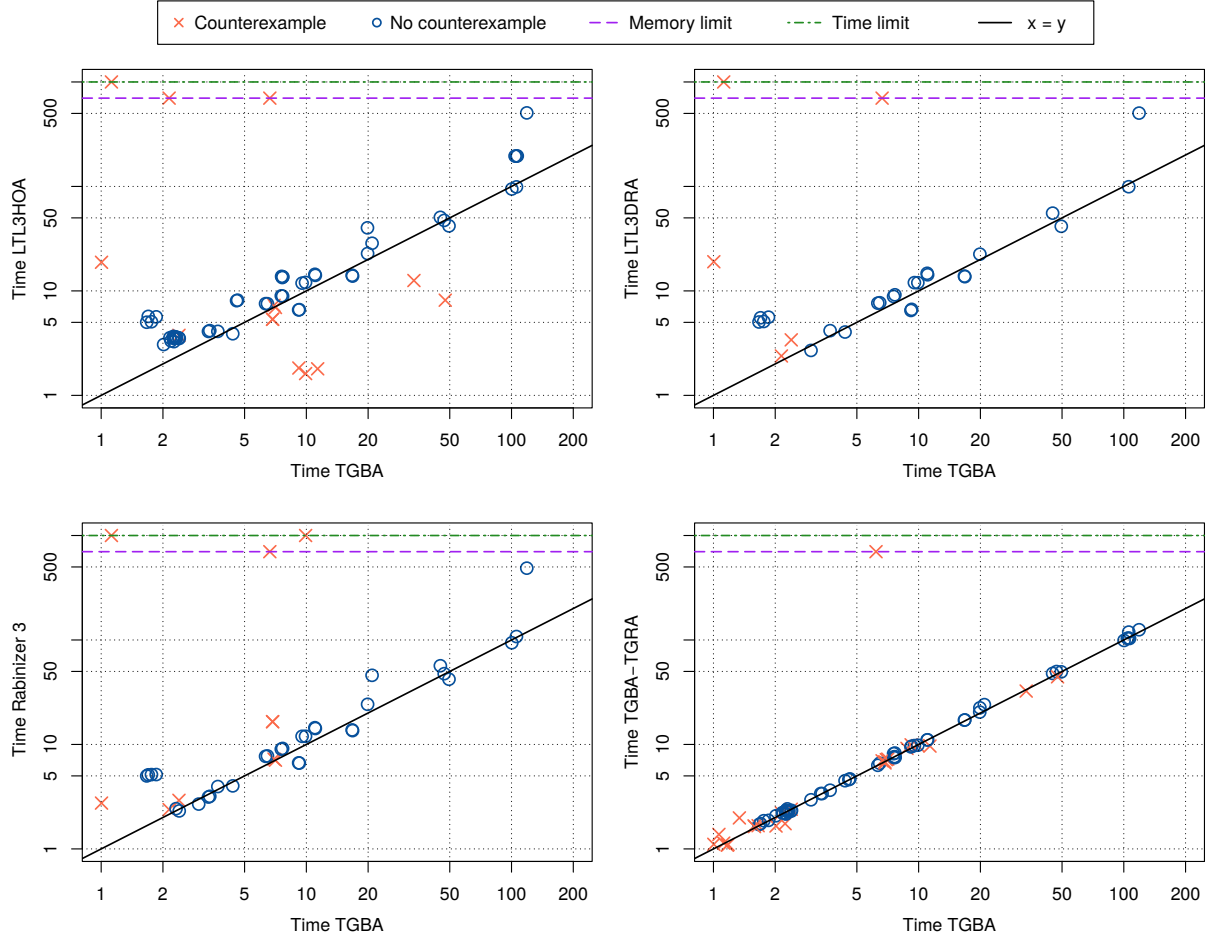

Figure 4: Time (in seconds) comparisons of the TGBA (x-axis) and the TGRA emptiness checks (y-axis), for various LTL to TGRA translations. Each point represents the time to perform an emptiness check using 16 cores, averaged over 10 runs. The TGRA algorithm performed faster for instances below the $x=y$ line.

faster by the GRA checking algorithm when the LTL3HOA automaton is used.

One remarkable instance is the one at (48,8) in the top-left scatter plot. The corresponding TGBA is a single-state automaton with one acceptance set, and the GRA is a single-state automaton with two pairs; one pair with a nonempty Fin set, and the other pair is equal to the TGBA. The GRA checking algorithm detects the counterexample while still searching in the first pair (the second pair is never considered), thus the co-Büchi acceptance leads to a 6 time improvement. The TGRA algorithm visits $59 \cdot 10^6$ unique

transitions, which is 12% of what the TGBA algorithm explores. Only 3% of the transitions were part of the Fin set.

The result at (1,19) in the top-left scatter plot is an instance where the TGRA algorithm performs significantly worse compared to the TGBA checking algorithm. This is (also) an instance where the TGRA equals a TcBA. One difference with the previous instance is that here, 30% of the transitions are part of the Fin set. This result suggests that Fin sets are only advantageous when a small fraction of the transitions in the product are part of a Fin set.

Table 2: Geometric mean sizes of the automata and products. $|\text{Aut}|$ denotes the number of states in the LTL automaton, $|\text{Pairs}|$ the number of GRPs in the TGRA, and $|\text{States}|$ and $|\text{Trans}|$ provide the sizes of the product automaton. We only used the data from experiments that did not contain a counterexample and were checked in *all* configurations (23 in total).

	$ \text{Aut} $	$ \text{Pairs} $	$ \text{States} $	$ \text{Trans} $
LTL3HOA	1.06	1.00	$1.80 \cdot 10^6$	$8.72 \cdot 10^6$
LTL3DRA	1.05	1.03	$1.79 \cdot 10^6$	$8.74 \cdot 10^6$
Rabinizer 3	1.64	1.03	$1.79 \cdot 10^6$	$8.74 \cdot 10^6$
TGBA-TGRA	2.08	1.00	$2.26 \cdot 10^6$	$11.88 \cdot 10^6$
TGBA	2.08	1.00	$2.26 \cdot 10^6$	$11.88 \cdot 10^6$

Cross-validation with TGBA seen as TGRA.

Since any TGBA can be trivially rewritten into a TGRA with an empty Fin set, we can use this to cross-validate our algorithm. The bottom-right scatter plot of Figure 4 shows the results for this comparison. Aside from one memory error (caused by unnecessarily allocating the data structure for Fstates , since there are no Fin sets), there are hardly any differences in the model checking times. It is not too surprising that the results are almost equal, since the TGRA checking algorithm does not have to track any Fstates as there are no Fin transitions in a TGBA. This means that the algorithm reduces to an SCC decomposition that tracks the acceptance marks, which is almost equal to the TGBA checking algorithm that we used to compare with.

We can (and should) avoid allocating memory for the Fstates data structure in case there are no Fin sets in the GRA. Then, this TGRA emptiness check can be used instead of the TGBA emptiness check as there is no reason to keep both algorithms if they perform equally.

5.3 Additional results

Sizes of the automata and products.

Table 2 summarizes information on the state-spaces from the experiments that do not contain a counterexample (thus the complete state-space is explored). One can see that the number of states in the automata is, on average, smaller for all GRAs (disregarding TGBA-TGRA) compared to TGBA and the automaton is approximately half the size of that of a TGBA for LTL3HOA and LTL3DRA. If we look at the mean state-space of the product, the sizes for the three GRAs are practically equal. From the Rabinizer 3 case we observe that a larger $|\text{Aut}|$ does not necessarily result in a larger number of states in the product. Also, the number of GRPs per GRA is almost always equal to one.

We further notice that the product size differs significantly from the GRAs and TGBA. The TGBA products contain approximately 26% more states and 35% more transitions. These numbers suggest that if the GRA checking algorithm would be improved to be (almost) as efficient as a TGBA checking one, there would be no reason to keep using TGBAs instead of TGRAs.

Checking GRPs in parallel.

In a number of cases we observe that the GRA consists of 2 GRPs (we have not encountered an instance that contained more than two pairs). In Section 3.1 we suggested

that these pairs could be checked in parallel instead of sequentially. We performed experiments to compare the two. In the case for products without counterexamples, there was no observable difference. In case there were counterexamples, the results varied more, but there does not seem to be a clear winner. Because the ‘parallel’ version does allocate significantly more memory (the memory consumption was almost doubled), we prefer checking the GRPs sequentially. Future work that checks more complicated GRAs may suggest reasons for choosing the alternative approach.

Scalability.

From [5, 6] we have that the TGBA checking algorithm achieves good scalability when increasing the number of workers, at least up to 64 cores. Initial experiments for the TGRA checking algorithm showed similar improvements, but the performance improvement starts to drop when increasing beyond 16 cores. The bottleneck of the algorithm is most likely caused by inserting and selecting states from the Fstates list. Future work could investigate whether the Fstates list can be further improved, or point out whether the bottleneck is a structural problem in the algorithm.

6. CONCLUSION

We introduced a multi-core, on-the-fly algorithm for explicit checking of emptiness on TGRAs. We showed that the algorithm is efficient in the sense that every state and transition only has to be visited once and reduces to an SCC decomposition in case there are no Fin sets in the TGRA.

Experiments show that, in general, a TGBA checking algorithm outperforms our new algorithm. This seems to be true in particular for cases where a large proportion of the product state-space is part of a Fin set for the TGRA.

Our experiments do suggest that using TGRAs for emptiness checks is advantageous in some scenarios. The product state-space for a TGRA is on average smaller than that of a TGBA. The results also suggest, presumably as a consequence, that our algorithm can outperform a TGBA checking algorithm if the successor computation procedure is a costly operation. The TGRA checking algorithm also seems beneficial in instances where only a small fraction of the state-space is part of a Fin set. Finally, the TGRA checking algorithm can be used as a replacement for a TGBA checking one, since the performance on checking TGBAs is practically equal.

Future work includes further improving the TGRA checking algorithm (there are several variations possible), performing additional experiments, and comparing this technique (in different contexts) with related work. Perhaps a preprocessing step could suggest when the algorithm should be applied on a TGRA and when on a TGBA.
